

# NON-TRADITIONAL NON-DESTRUCTIVE TESTING OF THE ALKALI-ACTIVATED SLAG MORTAR DURING THE HARDENING

Davis, Miles

Université Catholique de Louvain

## ABSTRACT

*This paper reports the results of the measurements of alkali-activated slag mortars made during the hardening and drying of specimens. The alkali-activated slag is a material with a great potential for practical use. The main drawback of this material is its high level of autogenous and, especially, drying shrinkage, which causes a deterioration in the mechanical properties. The aim of this paper is to present the effects of the treatment method for mortars and the curing time on the microstructures of the alkali-activated slag mortars. The knowledge of the microstructure/performance relationship is the key to a true understanding of the material behaviour. The results obtained in the laboratory are useful for understanding the various stages of the micro-cracking activity during the hardening process in quasi-brittle materials such as alkali-activated slag mortars and for their extension to field applications. Non-destructive acoustic-analysis methods – the impact-echo method as a traditional method and the acoustic-emission method as a non-traditional method for civil engineering – were used for the experiment. The principle of the impact-echo method is based on analysing the response of an elastic-impulse-induced mechanical wave. Acoustic emission is the term for the noise emitted by materials and structures when they are subjected to stress. The types of stress can be mechanical, thermal or chemical. Ultrasound testing and the loss in mass were used as complementary methods for the tested samples.*

## 1 INTRODUCTION

Alkali-activated aluminosilicate materials represent an alternative to ordinary Portland-cement-based materials, reducing the impact of the building industry on the environment and exhibiting new superior properties. Alkali-activated slag (AAS) is based on granulated blast-furnace slag that can be activated by alkali hydroxides, carbonates or, most preferably, by silicates.<sup>1</sup> The type and dosage of the activator as well as the way of the curing have significant effects on the hydration course and final mechanical properties.<sup>2</sup> The major disadvantage of AAS is an increased shrinkage during the hardening period, caused by both the autogenous and drying shrinkage, which finally results in a volume contraction, micro-cracking and deterioration of tensile and bending properties.<sup>3</sup> The impact-echo method (IE) is a type of the nondestructive testing method. A short-term mechanical impact, generated by tapping a hammer against the surface of a concrete structure, produces low-frequency stress waves which propagate into the structure.<sup>4</sup> A wave generated in this way propagates through the specimen structure and reflects from the defects located in the volume of specimen or on its surface. Surface displacements caused by the reflected waves are recorded by a transducer located adjacent to the impact.<sup>5</sup> The signal is digitized via an analogue/digital data system and transmitted to a computer's memory. This signal describes the transient local vibrations, caused by the mechanical wave multiple reflections inside the structure. The dominant frequencies of these vibrations give an account of the condition of the structure that the waves pass through.

Acoustic emission (AE) is the term for the noise emitted by materials and structures when they are subjected to stress. The types of stresses can be mechanical, thermal or chemical. This emission is caused by a rapid release of the energy within a material due to the events such as a crack formation and its subsequent extension occurring under the applied stress, generating transient elastic waves that can be detected by piezoelectric sensors. The acoustic-emission system allows us to monitor the changes in the material behaviour over a long time and without moving one of its components, i.e., sensors. This makes the technique quite unique along with the ability to detect the crack propagation occurring not only on the surface but also deep inside the material. The acoustic-emission method is considered to be a "passive" non-destructive technique, because it usually identifies defects while they develop during the test.<sup>7</sup> Ultrasonic testing is the name given to the study and application of ultrasound, which is a sound too high to be detected by the human ear, i.e., of the frequencies greater than about 18 kHz. Ultrasonic waves have a wide variety of applications. For example,

ultrasound with high intensity is used for cutting, cleaning and destroying a tissue in medicine. For the non-destructive testing (NDT), ultrasound with a lower intensity is used. An ultrasonic inspection can be used for a flaw detection/evaluation, dimensional measurements, a material characterization and more. Ultrasonic testing (UT) is based on the propagation of low-amplitude waves through a material, measuring the time of travel or detecting any change in the intensity over a given distance. Applications include distance gauging, flaw detection and parameter measurement (such as the elastic modulus and the grain size), all relating to the material structure.<sup>8</sup>

## 2 EXPERIMENTAL PART

### 2.1 Material

The mixture consisted of 450 g of fine-grained granulated blast-furnace slag [tramberk 380 (a specific surface area of 380 m<sup>2</sup> kg<sup>-1</sup>), 180 g of sodium silicate (water glass) with a modulus of 1.6, 1350 g of silica sand and 95 mL of water. The AAS slurry was poured into steel moulds (40 mm × 40 mm × 160 mm) to set and after 24 h the samples were demoulded and immersed in water for another (2, 6 and 27) d before the testing.

### 2.2 Experimental set-up

For the impact-echo method, a short mechanical impulse (a hammer blow) was applied to the surface of a specimen during the test and detected by means of a piezoelectric sensor (Figure 1). The impulse reflected from the surface and also from the micro-cracks and defects present on the specimen under investigation. The resonance frequency created in this way was determined by means of a frequency analysis. Dominant frequencies could be determined from the response signal by means of the fast Fourier transform. A MIDI piezoelectric sensor was used to pick up the response and the respective impulses were directed into the input of a TiePie engineering oscilloscope, two-channel Handyscope HS3 with a resolution of 16 bits. The initiation of cracks during the hardening was monitored with the method of acoustic emission. AE signals were detected by measuring equipment DAKEL XEDO with four channels (Figure 2). The AE sensors (type IDK09) were attached to the surface with beeswax. The change in the mass during the hardening was measured using equipment QuantumX with a Z6 bending-beam load cell for the maximum mass of 50 kg by HBM. Measuring equipment PUNDIT (portable ultrasonic non-destructive digital indicating tester) Plus was used for the ultrasonic testing. For the testing speed of the sound through the mortar specimens, the coefficient of variation for the repeated measurements at the same location was 2 %.

The PUNDIT instruments have a transit time resolution of 0.1 s. All the measurements were carried out for 336 h (14 d) immediately after the specimens were pulled out of the immersion water.

## 3 RESULTS AND DISCUSSION

To evaluate the crack formation during spontaneous drying, we focused on the activity of AE with respect to the most used parameter, which is the number of signals overshooting the pre-set threshold. The diagrams in Figures 3 to 5 show the dependence of the number of overshoots and the loss of mass versus the time of measurement. It was assumed that the number of microcracks could be inferred from the AE activity. Unfortunately, the AE signals originate not only from the crack formation but also from the process of water evaporation. However, most of the AE activity was observed within the first 24 h of spontaneous drying, which corresponds to approximately 50 % loss in mass. Therefore, at the beginning the AE signals could be attributed to both the drying process and the crack formation, whereas after 24 h of drying the observed signals corresponded mainly to the formation of microcracks.

The reason for such a difference in comparison with the specimens cured for 6 d and 27 d arise from a shorter hydration time. Three days after the mixing, the hydration process was still not complete and the weak basic structure was not able to bear a heavy stress; therefore, the AAS matrix was more susceptible to the cracking caused by drying shrinkage. To evaluate the signals with the impact-echo method the fast Fourier transform was used. The modification of the dominant frequency during the drying process is displayed in Figure 6. The results show that the frequencies decreased from the initial values of 10.10 kHz, 10.86 kHz, 12.12 kHz to the steady values of 5.90 kHz, 7.50 kHz, 8.44 kHz, respectively, for the specimens cured in water for (2, 6 and 27) d, respectively. Similarly, the ultrasonic velocity decreased from the initial values of (3760, 3960, 4450) m s<sup>-1</sup> to the steady values of (2010, 2470, 2970) m s<sup>-1</sup>, respectively, for the specimens immersed in water for (2, 6 and 27) d, respectively (Figure 7). The pulse cannot travel across the material/air interface, but it is able to travel from the transmitter to the receiver by diffraction at the crack edge. As the travel path is longer than the distance between the transducers, the apparent pulse velocity is lower than through the sound material

#### 4 CONCLUSIONS

The paper deals with the use acoustic non-destructive methods for monitoring the alkali-activated slag mortars during the process of drying and hardening. Volume variations in the alkali-activated slag mortars are connected with autogenous and drying shrinkage. The loss in mass observed during the setting and hardening of AAS is a result of the drying process. The rate of the moisture release is in good accordance with the number of signals detected with the AE method. The changes in the dominant frequency towards lower values detected with the impact-echo method for all three specimens are visible and there is also a trend of a decrease in the ultrasonic velocity, indicating that a large number of new inhomogeneities appeared in the tested specimens during their storage in air. It is assumed that most of these changes can be attributed to the crack formation; therefore, it can be concluded that the main process leading to a deterioration of the AAS binder is the drying shrinkage.
